3Chemistry Administration, Cairo, Egypt.

The rate of H₂ production was investigated during the dissolution of Zn in 0.5 M HCl in the absence and presence different concentrations of 5-amino-4-imidazolecarboxamide (AIC). Different techniques such as gasometry, electrochemical and scanning electron microscope are used. The data indicated that the rate of hydrogen evolution was increased with the inundation time and temperature and was mitigated with the presence of AIC inhibitor. The electrochemical impedance spectroscopy showed that AIC introduced an inhibitive film that can control the rate of corrosion of zinc. Polarization data indicated that AIC acted as a surface-active molecule that behaves as a mixed-type inhibitor. The free energy of adsorption and adsorption-desorption equilibrium constants were deduced and discussed.

Keywords: Imidazole, Zinc, Corrosion inhibition, Hydrogen production, Potentiodynamic, Adsorption.

Introduction

Zn and zinc alloys are used in many applications, among which the chargeable batteries and steel galvanization for corrosion protection [1-4]. The importance of the corrosion study of Zinc and its alloys comes from the feasibility of production of hydrogen when these materials allowed being in contact with dilute acids [5-7]. Logically, this idea is important to produce hydrogen, avoiding storing problems, as a fuel used for operating fuel cells, as a sustainable alternative to energy. This idea deserves attention to the production of fresh hydrogen used in the operation of fuel cells without the need for a storage phase to avoid storage problems.

Organic bulky molecules containing heteroatoms such as O, S, N, P and unsaturated bonds are considered as effective inhibitors that can tolerate the metal dissolution process through an adsorption step [8-14]. The heteroatoms of inhibitor molecules are rich with lone pairs of free electrons, which are considered as active sites available for adsorption on the metal surface forming a protective layer that keeps the metal surface from the destructive effect of the surrounding media.

Among the several classes of organic compounds, imidazole derivatives were found as better inhibitors against corrosion for many metals and alloys in the aqueous solutions [15-20]. Imidazole and imidazolecarboxamide derivatives are classified as an important type of organic inhibitors. This is due to the presence of several N atoms, π- electrons of aromatic rings and the electronegative O atom of the carbonyl group that may be attached within the molecule [15-18] easy to adsorb on the metal to form a protective film. The inhibition activity of different types of inhibitors towards the corrosion of zinc and H₂ production in acidic media has been rarely investigated [17-22]. Therefore, the main goal is to evaluate 5-amino-4-imidazolecarboxamide (AIC) as a corrosion inhibitor towards the dissolution of Zn and...
controller for \( \text{H}_2 \) production in 0.5 M HCl solution. Chemical (gasometry) and electrochemical (Tafel and EIS) techniques, complemented by surface investigations using SEM techniques were used.

**Experimental**

### Materials and electrolyte

#### Inhibitor preparation

Zinc sheet 99.99 % pure (Johnson-Matthey, UK) had been cut in coupons with dimensions 1.8, 3.7 and 0.3 cm for \( \text{H}_2 \) production study. For electrochemical studies, a Zn rod was used as a working electrode entrenched in a glass tube with an epoxy resin leaving an uncovered cross-section area of 0.32 cm\(^2\). Before each run, the Zn specimen was mechanically polished using different grades of emery papers. The specimen washed by doubly distilled water and degreased with acetone before inundation in the acid solution. 5-Amino-4-imidazolecarboxamide (AIC), Merck, was used as an inhibitor for corrosion of zinc. All experiments were done at 25 ± 1°C, except those carried to investigate the effect of temperature on the corrosion rate.

A Zn sheet with purity 99.99 % (Johnson-Matthey, UK) was cut into similar samples with dimensions 2.0 cm x 5.0 cm x 0.3 cm which were used for hydrogen measurement. For the electrochemical method, a zinc rod (working electrode, \( \text{WE} \)) has the same chemical composition was entrenched in epoxy resin with the free surface area of 0.28 cm\(^2\) was used. The Zn surface was, successively, abraded with different grades of fine emery papers up to mirror finish. Then, it was washed with bi-distilled water, followed by rinsing with a degreasing solvent, washed repeatedly with bi-distilled water, and finally immersed in the test solution. A fresh 0.5 M hydrochloric acid aqueous solution was prepared using 37% HCl (BDH) and bi-distilled water. The inhibitor concentrations varied between 1.0 x 10\(^{-6}\) and 2.5 x 10\(^{-5}\) M freshly prepared in 0.5 M HCl before running the experiment.

#### Experimental techniques

The volume of the collected \( \text{H}_2 \) gas was calculated per unit area of Zn specimen at different inundation times using gasometry apparatus as reported before [8, 21, 22]. Potentiodynamic polarization and EIS study, under static conditions, at 25°C, were done using a Volta lab 80 (PGZ 402) potentiostat with Volta master 4 software. Three electrodes system consists of Zn rode as \( \text{WE} \), a pure platinum sheet as an auxiliary electrode and a saturated calomel electrode as a reference electrode were used. The Zn electrode was immersed in the test solution for about 2 h before polarization and EIS measurements to establish steady-state potential, \( E_{\text{st}} \). The \( E-I \) curves were obtained by sweeping the electrode potential in the potential range from ± 200 mV relative to the steady-state potential, \( E_{\text{corr}} \). The corrosion current density, \( I_{\text{corr}} \) is performed by extrapolating the linear portions of the cathodic and anodic branches back to their intersection at \( E_{\text{corr}} \). Electrochemical impedance spectroscopy, EIS curves were obtained by employing a frequency range of 100 kHz to 0.1 Hz using a signal amplitude of 5 mV using AC signals at open circuit potential, \( E_{\text{corr}} \).

#### Surface investigation

The surface morphology of some corroded Zn specimens (1 cm x 1 cm) was investigated before and after immersing for 2 hr in both uninhibited (0.5 M HCl) and inhibited (0.5 M HCl + 1x10\(^{-5}\) M AIC inhibitor) solutions using

scanning electron microscope, SEM. The used SEM was a Jeol type, JSM-5410 (Japan), with an accelerated voltage of 25 kV and a working distance of 20 mm was used.

Results and Discussion

Gasometry study

The inhibition effect of 5-amino-4-imidazolecarboxamide (AIC) towards the corrosion of Zn in HCl, was investigated through the variation in the volume of the evolved hydrogen gas ($V$) with the inundation time, $t$. Figure 1 depicted $V$-$t$ curves of Zn in 0.5 M HCl solutions without and with various additives of AIC, at 25°C. The decrease in the volume of the evolved H$_2$ gas in presence of AIC inhibitor is due to the reduction in the corrosion process. The rate of the H$_2$ gas production can be determined from the slope of the $V$-$t$ relation [23, 24]. It is clear that the H$_2$ gas initiates to evolve after an incubation period, at which the protective passive film is destroyed by the effect of Cl$^-$ ions [24]. The incubation period is increased as the AIC inhibitor concentration is increased. Such behavior would confirm the presence of a protective film. On the other hand, the rise in the temperature will shortage the incubation period due to a corrosion acceleration effect [25].

The variation in the rate of H$_2$ production, $r_{\text{corr}}$, with log $C_{\text{inh}}$, at different temperatures is shown in Fig. 2. It is clear that the decrease in $r_{\text{corr}}$ with log $C_{\text{inh}}$ shows a sigmoid S-curve relation. Such behavior is similar to an adsorption isotherm which indicate that AIC inhibitor could be adsorbed on Zn surface decreasing the corrosion rate of Zn [23, 24].

The surface coverage, $\theta$, and the inhibition efficiency, $\eta$ % are calculated from the corrosion rate values in the absence and presence of the inhibitor solution, $r_{\text{corr}}$ and $r'_{\text{corr}}$, respectively, according to the following equations [24-27]:

\[ \theta = \frac{r_{\text{corr}} - r'_{\text{corr}}}{r_{\text{corr}}} \]  
\[ \eta \% = \frac{r_{\text{corr}} - r'_{\text{corr}}}{r_{\text{corr}}} \times 100 \]

The values of $\theta$ and $\eta$ % at different concentrations of AIC are included in Table 2. These values are increased with increasing the concentration of AIC and are decreased with rising the solution temperature. Such data confirms the adsorption-desorption of AIC molecules on Zn surface, at higher temperatures, which proves the physically adsorbed mechanism [28].

Polarization study

The anodic-cathodic potentiodynamic polarization curves of Zn in 0.5 M HCl solution without and with various additions of AIC, at 298K are depicted in Fig. 3. It is noted that the corrosion current densities are reduced in the presence of AIC due to an overvoltage effect.

TABLE 2. Values of corrosion rate, $r_{corr}$ (ml cm$^{-2}$ min$^{-1}$), surface coverage, $\theta$, and inhibition efficiency, $\eta$ %, of different concentrations of AIC for corrosion of Zn in 0.5 M HCl, at different temperatures.

accompanying each of the anodic and cathodic processes. This behavior could prove that the mechanism of Zn dissolution and H₂ production are under activation-controlled process, and not altered by the presence of inhibitor [28, 29].

The values of the corrosion current densities in the absence, \( I_{corr}^0 \), and presence of AIC inhibitor, \( I_{corr} \), are used to calculate the surface coverage, \( \theta \), and the inhibition efficiency \( \eta' \) %, respectively, according to the following equations [25-29].

\[
\theta = \frac{I_{corr}^0 - I_{corr}}{I_{corr}^0} \\
\eta' = \frac{I_{corr}^0 - I_{corr}}{I_{corr}^0} \times 100
\]

The data of steady-state potential, \( E_{corr} \), anodic and cathodic Tafel slopes (\( \beta_a \) & \( \beta_c \)), \( \theta \) and \( \eta' \) % are tabulated in Table 3. It is noted that \( I_{corr} \) is lowered while each of \( \theta \) and \( \eta' \) % are increased with AIC concentration due to the inhibitive effect of AIC towards the corrosion of Zn.

In addition, the non-significant changes in the values of \( \beta_a \) and \( \beta_c \), beside the little displacement in \( E_{corr} \) (6-30 mV SCE), which is < 85 mV; confirm that AIC molecules behaved as a mixed inhibitor [30-35].

**Electrochemical impedance spectroscopy measurements**

Figure 4 depicted the Nyquist diagrams of Zn in 0.5 M HCl without and with different concentrations of AIC inhibitor. The Nyquist plots show a single depressed capacitive semicircle for both blank and AIC inhibitor solutions. The depressed semicircles, which probably correspond to Nyquist diagrams is characteristic of solid electrodes that exhibit frequency dispersion due to the roughness and other inhomogeneity of the metal surface [29]. The single semicircular capacitive loop is considered as an indication of a single charge transfer process controlling the Zn corrosion reaction [29]. This shape was unaffected in the presence of AIC at different concentrations revealing that the corrosion process has an activation-controlled nature does not change, in agreement with polarization investigation [29, 36]. The centers of these depressed loops were displaced below the real axis. This phenomenon may be related to the frequency dispersion. Such behavior could be referred to the frequency dispersion influence of the interfacial impedance and the inhomogeneous Zn surface [37]. It is ordinarily attributed to the presence of coarseness roughness and inhibitor adsorption [38, 39]. Moreover, the presence of AIC inhibitor increased the diameter of the capacitive loops than that of free HCl solution, that the surface of zinc metal is covered by a barrier film in presence of AIC inhibitor and impedes the corrosion of Zn [38].

The impedance spectra are investigated by fitting the experimental data to the equivalent circuit as given in Fig. 5. The impedance parameters like the charge transfer resistance (\( R_c \)), the solution resistance (\( R_s \)), double layer capacitance, \( C_{dl} \), and percentage inhibition efficiency (\( \eta' \) %) are represented in Table 4. It is obvious that \( R_c \) and \( \eta' \) % values are increased with AIC concentration confirming the formation of a protective film on the metal/solution interface [39, 40]. The values of electrical double layer capacitance, \( C_{dl} \), was inversely proportional with \( R_c \) according to the relation:

\[
C_{dl} = \left( \frac{1}{2 \pi f R_c} \right) \left( \frac{1}{A} \right)
\]
where $f_{\text{max}}$ is the frequency at maximum imaginary impedance.

The values of $C_{dl}$ were reduced in presence of AIC inhibitor (Table 4), due to the rise in the intensity of the electrical double layer around the protective film and/or decrease the local dielectric constant due to the permutation of $\text{H}_2\text{O}$ molecules at the Zn surface by the adsorbed AIC molecules [39].

Also, the reduction in $C_{dl}$ values in presence of AIC is inversely proportional to the double layer thickness, $\delta$, according to Helmholtz model [40, 41].

$$C_{dl} = \left( \frac{\varepsilon \varepsilon_0 \delta}{\varepsilon_0} \right)$$  \hspace{1cm} (6)

where $\varepsilon$ is the dielectric constant, S is the electrode surface area and $\varepsilon_0$ is the air permittivity. The lower values of $C_{dl}$ with higher additions of AIC inhibitor may be attributed to the efficacious adsorption process. This fact suggests that the inhibitor molecules could firstly be adsorbed on Zn surface, covering the active sites.

The values of inhibition efficiencies, $\eta'' \%$, (Table 4), are obtained from $R_{ct}$ values using the equation [35]:

$$\eta'' \% = \left( \frac{R_{ct} - R_{ct}'}{R_{ct}} \right) \times 100$$  \hspace{1cm} (7)

where $R_{ct}$ and $R_{ct}'$ are the electric charge transfer resistance for Zn in 0.5 M HCl with and without AIC, respectively. The values of $\eta'' \%$ increase with the rise in the AIC concentrations to reach a maximum efficiency (76.8 %) at 2.5x$10^{-5}$ M. The above results indicate that with an increase in AIC concentration a more protective film is formed on the Zn surface. These data confirm the agreement between the results obtained by EIS and other techniques.

**Temperature study**

The study of temperature on the dissolution of Zn in 0.5 M HCl in the absence and presence of different concentrations of AIC inhibitor is used to determine the rate of hydrogen production, $r_{corr}$ at different temperatures by gasometric

**Fig. 4. EIS Nyquist for Zinc in 0.5 M HCl in the absence and presence of different concentrations of AIC, at 298 K.**
Fig. 5. Equivalent circuit model used for simulation of impedance spectra.

The data indicated that the value of \( r_{\text{corr}} \) at different concentrations of AIC inhibitor was increased with a rise in temperature. Temperature accelerates the rate of H\(^+\) ions diffusion and enhances the rate of H\(_2\) production [42]. The relatively lower values of \( r_{\text{corr}} \) in case of AIC inhibitor, establishes the mitigation of H\(_2\) production, without altering the mechanism of the dissolution reaction.

The apparent activation energy, \( E_a \), required for the dissolution of zinc metal and production of H\(_2\) gas can be calculated using Arrhenius equation [42, 43]:

\[
E_a = \frac{R \ln \left( \frac{A}{n} \right)}{h} \tag{8}
\]

where \( r_{\text{corr}} \) is the rate of hydrogen production, \( A \) represents the Arrhenius factor, \( T \) is the absolute temperature and \( R = 8.314 \text{ J mol}^{-1} \text{K}^{-1} \) is the universal gas constant.

Plotting of log \( r_{\text{corr}} \) against \( T^{-1} \) in case of free 0.5 M HCl and 0.5 M HCl containing different concentrations of AIC inhibitor is depicted in Fig. 6. The obtained plots gave straight lines relation, which confirms Arrhenius equation. The activation energies \( E_a \) were evaluated from the slope of the straight-line plots. The calculated values of activation energy are listed in Table 5. The obtained value of \( E_a \) for Zn in the blank solution is 11.40 kJ/mol. In presence of AIC inhibitor, \( E_a \) varied between 15.72 and 29.45 kJ/mol according to the inhibitor concentration. The increase in the values of \( E_a \) in presence of AIC inhibitor may be attributed to the presence of inhibitive film formed from AIC molecules on the zinc metal surface [44-46]. This observation further supports the physisorption mechanism [42, 47]. Further inspection of Table 5 also revealed that \( E_a \) increases with increase in the AIC inhibitor concentration, which supports the physical adsorption mechanism [42].

The values of \( r_{\text{corr}} \) (ml\(^1\)cm\(^{-2}\)min\(^{-1}\)) at different temperatures are used to locate the values of apparent enthalpy, \( \Delta H_a \), and entropy, \( \Delta S_a \) of activation for the formation of the activation complex, using the following equation [42-45]:

\[
r_{\text{corr}} = \frac{RT}{N h} \exp \left( \frac{\Delta S_a}{R} \right) \exp \left( -\frac{\Delta H_a}{RT} \right) \tag{9}
\]

where \( R \) is the universal gas constant, \( N \) is the Avogadro’s number and \( h \) is Planck’s constant. From the linear plot of log \( (r_{\text{corr}}/T) \) vs \( T^{-1} \), (Fig. 7), \( \Delta H_a \) and \( \Delta S_a \) were calculated using the slope and the intercept values, successively, (Table 4). The positive sign of \( \Delta H_a \) reflects the endothermic nature of Zn dissolution in the free acid and inhibitive solutions. The rise in the \( \Delta H_a \) in case of AIC confirms the difficulty of Zn dissolution process in presence of AIC inhibitor [42]. The negative sign of \( \Delta S_a \) (Table 5) suggests that the activated complex in the rate-determining step demonstrates a combination rather than a dissociation step, supporting a lessening in disorder happens through the transition state where the reactants changed to the activated complex [47].

**Adsorption behavior**

The adsorption of inhibitor molecules at the corroded metal surface in aqueous solutions can be attributed to the presence of some of the surface-active centers rich with free electrons. A substitution process during the adsorption where a reciprocation between adsorbed H\(_2\)O molecules and inhibitor molecules occurs.

The surface coverage, \( \theta \), appreciated from the data of gasometry measurements is used as a function of inhibitor concentration, to investigate the type of adsorption isotherm. The isotherm accounts for the nature of the interaction between the metal and inhibitor molecules. In our study,

the best-fit isotherm was Langmuir-model. The applicable model can be achieved from the relation [43]:

\[
\frac{C_{\text{inh}}}{\theta} = \frac{1}{K_{\text{ads}}} + C_{\text{inh}}
\]

(10)

Experimental results of \( C_{\text{inh}}/\theta \) vs \( C_{\text{inh}} \), at different temperatures, give straight lines, as shown in Fig. 8. The obtained correlation coefficient \( (r^2 > 0.99) \) confirms this type of isotherm. The corresponding linear regression parameters including the linear correlation coefficient \( r^2 \), slope, intercept and \( K_{\text{ads}} \) are collected in Table 5. The values of each of the slope and \( r \) are nearly equal one which confirms the adsorption of AIC on Zn surface follows to Langmuir’s model. The higher values of \( K_{\text{ads}} \) for AIC inhibitor are consistent with the results of Morad when used other inhibitors for corrosion of Zn in acidic medium [48]. This reflects the interaction of the inhibitor with the metallic surface [48] confirming strong adsorption of AIC molecules on the Zn surface. The drop in \( K_{\text{ads}} \) values with temperature (Table 6) indicates a decrease in the adsorptive ability due to the desorption of AIC from Zn surface at the higher temperature.

Adsorption thermodynamic parameters

The standard free energy of adsorption, \( \Delta G_{\text{ads}}^o \), can be calculated from the values of the adsorption equilibrium constant, \( K_{\text{ads}} \) (Table 6), according to the equation [32]:

\[
K_{\text{ads}} = \frac{1}{\theta} \exp\left(-\frac{\Delta G_{\text{ads}}^o}{RT}\right)
\]

(11)

where 55.5 represents the molar concentration value of \( \text{H}_2\text{O} \) in mol/L and \( R \) is the universal gas constant. The negative sign of \( \Delta G_{\text{ads}}^o \) confirms the spontaneity of the adsorption process. Generally, when the values of \( \Delta G_{\text{ads}}^o \) reach -40 kJ mol\(^{-1}\) or more negative

suggest the chemical adsorption process. In case of $\Delta G_{\text{ads}}^{\circ} = -20 \text{ kJ mol}^{-1}$ or less negative will confirm the physical adsorption [33, 34]. The calculated values of $\Delta G_{\text{ads}}^{\circ}$ (Table 7) were found to be -57.11, -44.07, -45.19, -45.19 and -46.09 kJ mol$^{-1}$ at 25, 35, 45, 55°C, successively. The obtained values of $\Delta G_{\text{ads}}^{\circ}$ proved that AIC inhibitor is easy to adsorb on zinc surface according to chemical adsorption process. From the other point of view, the increase in the activation energy, $E_a$, with AIC inhibitor concentration indicates two types of interactions (chemisorption and physisorption) are involved in the inhibition process [49].

Adsorption thermodynamic parameters are employed to elucidate the adsorption behavior of AIC on Zn surface. The standard enthalpy of adsorption $(\Delta H_{\text{ads}}^{\circ})$ can be calculated from Van’t Hoff equation [48].

$$\ln K_{\text{ads}} = \frac{\Delta H_{\text{ads}}^{\circ}}{2.303RT}$$

The indefinite integration of Eq. 12 can give [49]:

$$\log K_{\text{ads}} = \frac{\Delta H_{\text{ads}}^{\circ}}{2.303RT} + \text{constant}$$

The values of log $K_{\text{ads}}$ are plotted against $T^{-1}$, (Fig. 9), to give a straight-line relation, with a slope equal to $-\Delta H_{\text{ads}}^{\circ}/2.303R$. The value of $\Delta H_{\text{ads}}^{\circ}$ is found to be -3.92 kJ/mol (Table 7). Actually, when $\Delta H_{\text{ads}}^{\circ} > 0$, an endothermic adsorption process; the chemical adsorption process is predominant. On the other hand, for $\Delta H_{\text{ads}}^{\circ} < 0$, an exothermic adsorption process could be attributed to physical adsorption, chemical adsorption or a mixture of both processes [50]. The negative sign of the obtained $\Delta H_{\text{ads}}^{\circ}$ indicates the exothermic nature of adsorption of AIC on Zn surface in HCl. From another side, the value of enthalpy is < 41.8 kJ mol$^{-1}$, which confirms that the adsorption of AIC on Zn surface is a combination of physisorption and chemisorption types, i.e. a mixed type [43, 49].

The standard adsorption of entropy, $\Delta S_{\text{ads}}^{\circ}$, can also be obtained from the following equation [50, 51]:

\[
\Delta S_{\text{ads}}^{\circ} = \frac{\Delta H_{\text{ads}}^{\circ} - \Delta G_{\text{ads}}^{\circ}}{T}
\]

The values of $\Delta S^0_{ads}$ can be calculated and collected in Table 7. The positive values of $\Delta S^0_{ads}$ suggest that adsorption process is linked with a rise in the disorder of the system and this case may be due to the adsorption of only one inhibitor molecule by desorption of more than one water molecule [52].

**Surface morphology**

Scanning electron microscope study has been used to examine the surface of some corroded Zn samples to understand the surface properties and morphology during the of zinc surface after polishing using different grades of emery papers (Fig. 10 A). The SEM micrograph for zinc surface after immersion for a period of 1hr in 0.5 M HCl solution devoid of and containing 1x $10^{-5}$ M AIC inhibitor are shown in Fig. 10 B and C, respectively. The SEM micrograph of the corroded Zn sample in 0.5 M HCl solution (Fig. 10 B) shows uniform highly damaged Zn surface, which is covered by the products of corrosion. The extended corrosion area might supposedly have been created from smaller pits prolonged evenly laterally, as well as, internally so that the large attacked area is formed. In contrast, the presence of the AIC inhibitor clarified less damage surface with some numbers of pits on zinc surface (Fig. 10 C). Therefore, the existence of AIC inhibitor decreased the rate of corrosion of zinc in HCl.

**Inhibition mechanism**

The inhibition effect 5-amino-4-imidazolcarboxamide (AIC) towards Zn/HCl interface is supposed to be related to the molecule adsorption through the free electron pairs located on N and O atoms of AIC inhibitor molecules interface to form a defensive film. The formed inhibitive film protects the Zn surface from the aggressive effect of HCl. The adsorption process includes the replacement of $H_2O_{ads}$ from the zinc metal surface in the aqueous phase by AIC molecules, $AIC_{aq}$:

$$AIC_{aq} + xH_2O_{ads} \rightleftharpoons AIC_{ads} + xH_2O_{aq} \quad (15)$$

where $x$ represents the number of $H_2O_{ads}$ substituted by one molecule of $AIC_{ads}$. $AIC_{ads}$ molecules can adsorb on the Zn surface via the free electrons pairs located on one O atom and four N atoms without ignoring the effective conjugated role of the $\pi$-electrons system in the molecule, confirming chemical adsorption mechanism [53].

From another point of view, the AIC inhibitor molecules are suggested to be represented by the protonated form in presence HCl aqueous solutions [HAIC]$^+$. The equilibrium between the cationic and neutral form of AIC forms can be represented by:

$$AIC + HCl \rightleftharpoons [HAIC]^+ + Cl^- \quad (16)$$

Generally, the surface of zinc metal is considered to carry a positive charge in acid solutions [48], which assist the formation of $ZnCl_{ads}^-$ on the metallic surface. An immoderate negative charge is formed on Zn surface towards the solution interface, which facilitates the adsorption of protonated inhibitor molecules, [HAIC]$^+$, onto the metal zinc surface according to physical adsorption model reducing the corrosion process.

---

Conclusions

Different chemical and electrochemical techniques were used to study the corrosion of zinc and H₂ production in 0.5 M HCl in the absence and presence of different concentrations of 5-amino-4-imidazolocarboxamide (AIC). The experimental data revealed the following conclusion:

1. The rates of zinc corrosion and H₂ production were found to increase with the inundation time and the solution temperature.
2. Different additions of 5-amino-4-imidazolocarboxamide decrease the rates of zinc corrosion and H₂ production as indicated by the different experimental techniques.
3. Polarization data indicated that 5-amino-4-imidazolocarboxamide acted as a mixed inhibitor inhibiting both the anodic and cathodic reactions.
4. The inhibition process was based on the mechanism of adsorption of the inhibitor molecules on the metal surface through the free electrons of O atom and N atoms besides the role controlled by the π-electrons of the conjugated double bonds system.
5. The inhibition efficiency is increased with increasing inhibitor concentration and decrease with the temperature.
6. The adsorption process is a mixed-type including the physical and chemical processes according to Langmuir isotherm.
